HETEROGENEOUS PREFERENCES, MARKET
STRUCTURE AND NEW GOODS IN THE
ARGENTINEAN FROZEN FRIED POTATO
INDUSTRY

González Julia

Heterogeneous preferences, market structure and new goods in the Argentinean frozen fried potato industry¹

Julia González²

¹ This paper is a preliminary version of the author's Master degree thesis, and has been developed within the framework of a research project carried out jointly with M. Victoria Lacaze.

² Research fellow at Universidad Nacional de Mar del Plata, Argentina. Master in Economics student at Universidad de San Andrés, Argentina.

Heterogeneous preferences, market structure and new goods in the Argentinean frozen fried potato industry

Abstract

This article studies the preference structure of frozen fried potatoes consumers in Mar del Plata, Argentina, and the effect of changes in market structure and the addition of a new product on prices, market shares, and welfare. Heterogeneity in consumer preferences is found, driven by demographic characteristics. Consumer surplus would decrease with a merger between the two smaller firms of the market, and would increase if the market turned into a single-product firms industry. The results emphasize the importance of both agronomic issues and consumer preferences for the success of the introduction of a credence-attribute in a food industry.

JEL: [L11], [D12]

Resumen

Este trabajo analiza las preferencias por papas prefritas congeladas de los consumidores de Mar del Plata, Argentina, y el efecto de cambios en la estructura de mercado y la incorporación de un nuevo producto en precios, participación en el mercado y bienestar. Se encuentra heterogeneidad en las preferencias por diferencias en características sociodemográficas. El excedente del consumidor disminuiría ante una fusión entre las dos firmas más pequeñas, y aumentaría si el mercado fuera de firmas monoproducción. Se destaca la importancia tanto de los aspectos agronómicos como de demanda para el éxito de la incorporación de un atributo de confianza.

JEL: [L11], [D12]

1. Introduction

Frozen fried potatoes (FFP) are an extensively consumed food in developed countries. Although the FFP market has reached maturity in the United States, FFP consumption has rapidly grown in developing countries, which is related to the higher women's labor force participation rates, the higher frequency of eating-out, and other changes in working patterns. In Argentina, the FFP industry is characterized by high concentration and high degree of horizontal and vertical differentiation. Argentinean households' direct demand for FFP is primarily supplied by super and hypermarkets, even though restricted because of the high prices if compared with fresh potatoes. The FFP production accounts for 80% of the potatoes destined to industrial processing (Mateos, 2003). Besides, some transnational companies which produce FFP in Argentina have started to require potato farmers who supply them to certify the implementation of quality standards, which implies the incorporation of a new credence attribute in some Argentinean FFP. However there are virtually no research on the characteristics, evolution, and development of the domestic market of FFP in Argentina.

The study of differentiated-product markets is a key topic of the recent literature in empirical industrial organization. The Random Coefficients Discrete Choice Model (Berry, 1994; Berry et al., 1995), henceforth RCDCM, has gained importance in the study of market power, new goods, and changes in market structure of differentiated-product markets, because it allows to achieve flexible substitution patterns. Berry, Levinsohn and Pakes (1999) evaluate the impact of the voluntary export restraint of Japanese vehicles exported to the United States that was set up in 1981. Nevo (2000a, 2001) examines collusive pricing behavior and evaluates actual and hypothetical mergers in the ready-to-eat cereal industry. Petrin (2002) quantifies the effect of the introduction of the minivan into the U.S. automobile market.

The objective of this paper is to estimate consumers' preferences structure for FFP and to measure the effect of changes in market structure and the addition of a new attribute on prices, sales, and consumers' surplus. To achieve this objective, I first estimate a RCDCM of FFP and then I propose changes in the ownership matrix of the industry. Finally, a new

methodology for the evaluation of the introduction of a new product with a new attribute is developed, which combines stated and revealed preferences approaches. The rest of the paper is organized as follows. Section 2 outlines the theoretical framework of discrete choice models. Data, estimation, and identifying assumptions are presented in Section 3. Results are reported in Section 4. Lastly, Section 5 concludes the paper.

2. Discrete-choice logit models

Product differentiation as a research topic of agricultural economics dates back to the decade of the 1920s, when Waugh (1928) published his seminal work devoted to analyze the relationship between price and characteristics of vegetables in the United States. Later, Houthakker (1951-52) and Thail (1951-52) incorporated the product characteristics in their utility maximization models, while Lancaster (1966) postulated that it is the properties or characteristics of the good from which utility is derived. The Simple Logit Model (McFadden, 1973) makes use of this conceptual framework and solves some challenges that arise when estimating demand functions for differentiated products. Specifically, it overcomes the dimensionality problem by projecting the products onto a characteristics space. However, in this model all individuals are assumed to be identical except for the error term, which entails strong restrictions on elasticity coefficients. On the one hand, the own-price elasticities are almost perfectly proportional to prices when the market share of the outside good is close to one (McFadden, 1981). On the other hand, the cross-sensitivity of demand is the same regardless the good whose price changes, and therefore consumers substitute towards other products in proportion to market shares, without considering the similarity of their characteristics. More flexible substitution patterns are achieved with the Nested Logit Model, whose estimation requires a priori clustering of products; the cross-price elasticity coefficients are different between groups but equal within them. Finally, the RCDCM (full model) allows for flexible own-price elasticities driven by the different price sensitivity of different consumers, and for cross-price substitution patterns driven by product characteristics and not constrained by arbitrary segmentation of the market.

The rest of the section presents the RCDCM of demand, the assumed supply behavior, and a measure of welfare change. In general terms, the idea is to estimate the structural parameters that govern demand and supply and to use them to analyze the effects on welfare of counterfactual changes of FFP market structure.

3.1 Demand

Suppose $t = 1, \dots, T$ markets (as defined below) are observed, each with $i = 1, \dots, I$ consumers. The conditional indirect utility of consumer i from product j ($j = 1, \dots, J$) at market t is

$$(1) \quad u_{ijt} = x_j \beta_i^* - \alpha_i^* p_{jt} + \xi_j + \Delta \xi_{jt} + \varepsilon_{ijt}$$

where x_j is a K -dimensional (row) vector of observable product characteristics, p_{jt} is the price of product j in market t , ξ_j is the mean valuation of the unobserved product characteristics, $\Delta \xi_{jt}$ is a market specific deviation from this mean, and ε_{ijt} is a mean-zero stochastic term distributed i.i.d. with Type I extreme-value distribution. Finally, $(\alpha_i^* \beta_i^*)$ are $K + 1$ individual-specific coefficients, defined following the approach of Nevo (2001) as:

$$(2) \quad \begin{pmatrix} \alpha_i^* \\ \beta_i^* \end{pmatrix} = \begin{pmatrix} \alpha \\ \beta \end{pmatrix} + \Pi D_i + \Sigma v_i$$

$$v_i \sim N(0, I_{K+1})$$

where $(\alpha \beta)$ are the mean parameters of the utility function, D_i is a $d \times 1$ vector of observed demographic variables, v_i is a vector of normal random shocks in tastes,³ Π is a $(K + 1) \times d$

³ The vector v_i represents the unobserved individual characteristics (i.e., not available in the auxiliary dataset) that affect preferences.

matrix of coefficients that measure how the taste coefficients vary with demographics, and Σ is a scaling matrix.

The consumers may decide not to purchase any of the products, in which case they choose the “outside good”. Without this allowance a homogeneous price increase of all products does not change quantities purchased. The indirect utility from this outside option is

$$u_{i0t} = \xi_0 + \pi_0 D_i + \sigma_0 v_{i0} + \varepsilon_{i0t}$$

The mean utility of the outside good, ξ_0 , is not identified, so it is normalized to zero.

Let $\theta = (\theta_1, \theta_2)$ be a vector containing all parameters of the model. The vector $\theta_1 = (\alpha, \beta)$ contains the linear parameters and the vector $\theta_2 = (\Pi, \Sigma)$, the nonlinear parameters.⁴ Combining equations (1) and (2):

$$(3) \quad \begin{aligned} u_{ijt} &= \delta_{jt}(x_j, p_{jt}, \xi_j, \Delta \xi_{jt}; \theta_1) + \mu_{ijt}(x_j, p_{jt}, v_i, D_i; \theta_2) + \varepsilon_{ijt} \\ \delta_{jt} &= x_j \beta - \alpha p_{jt} + \xi_j + \Delta \xi_{jt}; \mu_{ijt} = [p_{jt}, x_j]' * (\Pi D_i + \Sigma v_i) \end{aligned}$$

where δ_{jt} represents the mean utility, which is common to all consumers, and $\mu_{ijt} + \varepsilon_{ijt}$ is a mean-zero heteroskedastic deviation from that mean that captures the effects of the random coefficients.

It is assumed that consumers purchase one unit of the good that gives the highest utility.⁵ This implicitly defines the set of individual-specific variables that lead to the choice of good j :

$$A_{jt}(x, p_t, \delta_t; \theta_2) = \{(D_i, v_i, \varepsilon_{it}) | u_{ijt} \geq u_{ilt} \forall l = 0, 1, \dots, J\}$$

Assuming ties occur with zero probability, the market share of the j th product as a function of the mean utility levels of all the $J + 1$ goods, given the parameters, is

$$(4) \quad s_{jt}(x, p_t, \delta_t; \theta_2) = \int_{A_{jt}} dP^*(D, v, \varepsilon) = \int_{A_{jt}} dP_D^*(D) dP_v^*(v) dP_\varepsilon^*(\varepsilon)$$

where $P^*(\cdot)$ denotes population distribution functions. The second equality is a consequence of an assumption of independence of D , v , and ε . Unlike the Simple Logit Model, in the full model the market share equations do not have an analytic closed form, therefore the integral given in equation (4) has to be computed numerically, as will be shown below.

Since the main data source includes aggregate sales data, heterogeneity can be modeled either by assuming a parametric distribution of $P^*(\cdot)$ (Berry, 1994; Berry et al., 1995) or as a function of the empirical nonparametric distribution of demographics (Nevo, 2001). I implement the second option in this paper, which allows us to assess the joint distribution of the demographic variables in D .

3.2 Supply

Suppose there are F firms, each of which produces some subset, \mathcal{F}_f , of the $j = 1, \dots, J$ different products. The profits for a firm f are

$$(5) \quad \Pi_f = \sum_{j \in \mathcal{F}_f} (p_j - mc_j) M s_j(p) - C_f$$

where $s_j(p)$ is the market share of product j , which is a function of the prices of all products, M is the size of the market,⁶ mc_j is the constant marginal cost of production, and C_f is the fixed cost of production. Assuming the existence of a pure-strategy Bertrand-Nash equilibrium in prices, and that the prices that support it are strictly positive, the price p_j of any product j produced by firm f must satisfy the first-order condition

$$(6) \quad s_j(p) + \sum_{r \in \mathcal{F}_f} (p_r - mc_r) \frac{\partial s_r(p)}{\partial p_j} = 0$$

⁴ The reason for distinguishing between linear and nonlinear parameters has to do with how they enter the model and the estimator, as will be shown below.

⁵ This is a reasonable assumption since most people consume only one kind of FFP at a time.

⁶ The market size defined in this model includes the share of the outside good, which allows keeping the market size fixed while still allowing the total quantity of products sold to increase. Therefore, the analysis of a hypothetical change in market structure is less sensitive to the exact definition of market size.

In vector notation, the first-order conditions become

$$(7) \quad s(p) + (\Omega.*\Delta)(p - mc) = 0$$

where Ω is the ownership matrix, whose element Ω_{jr} equals one if j and r are produced for the same firm, and zero otherwise. Δ is the derivative matrix, where $\Delta_{jr} = \partial s_r(p) / \partial p_j$, which is obtained when estimating the demand model. This implies a system of equations to compute the marginal costs, which are not observed:

$$(8) \quad mc = p + (\Omega.*\Delta)^{-1}s(p)$$

Equation (7) also provides an equation to predict counterfactual equilibrium prices, p^* :

$$(9) \quad p^* = \widehat{mc} - (\Omega^*.*\Delta)^{-1}s(p^*)$$

where \widehat{mc} are the estimated marginal costs, and Ω^* is the ownership matrix that represents the hypothetical market structure of the counterfactual scenario. When computing post-change equilibrium prices and market shares I make two important assumptions. First, I assume that the cost structure stays the same before and after the changes. Second, the derivative of shares with respect to prices, matrix Δ , also remains unchanged.

3.3 Consumer welfare

The measure I use to evaluate the changes in consumer welfare as a result of hypothetical scenarios is the compensating variation. Unlike the Simple Logit Model, this measure does not have an analytical solution for the full model when α_i^* in equation (1) is a function of income. In this case, the compensating variation of individual i , CV_i , has to be computed iteratively, and is equal to $-\Delta y_i$, where Δy_i solves

$$u_i(y_i, p) = u_i(y_i + \Delta y_i, p^*)$$

where y_i is the income of individual i and p is the vector of prices in the initial situation. In the case of the incorporation of the new product, the compensating variation is calculated in a slightly different way, as will be shown below. The mean compensating variation in the population is given by

$$(10) \quad CV = N \int CV_i dP_D^*(D) dP_v^*(v)$$

where N is the total number of consumers.

Two assumptions have to be made when computing these changes in consumer surplus. First, as with the observed characteristics, there is no change in the unobserved components, ξ_{jt} . Second, there are no changes in the utility from the outside good.

3. Data, estimation, and identifying assumptions

3.1 Data

The data required to consistently estimate the model previously described consist of the following variables: market shares and prices in each market (as defined below), product attributes, and demographic characteristics of individuals. Since I do not possess information about individual purchases, I match scanner data with an auxiliary database, which provides the distribution of demographic variables across population in each market, in order to identify the variable part of the coefficients.

The scanner database was provided by a traditional supermarket chain in Mar del Plata, Supermercados Toledo S. A., and consists of the value of monthly sales and the quantity sold for each product and each of the 23 branches of the supermarket, from July 2005 to December 2009. The city of Mar del Plata is located on the Atlantic Ocean coast, 400 kilometers (249 miles) south of Buenos Aires City, the capital city of Argentina. It is one of the major fishing ports, an important industrial area, and the biggest seaside beach resort in the country. With a population of roughly 600,000 inhabitants, Mar del Plata is the second largest city of Buenos Aires Province and the seventh largest Argentinean city, and is the main urban center of the major potato production area of the country, which is located in the

southeast Province of Buenos Aires. Figure 1 shows the geographical distribution of the supermarket branches, confirming their widespread allocation in the city.

The sales data cover 18 FFP products supplied by three firms (McCain, Alimentos Modernos, and Granja del Sol) through four brands (McCain, FarmFrites, Granja del Sol, and RapiPap), and are classified in six segments or varieties (bastón, golden longs, noisette, rondelles, smiles, and croquettes) and offered in several container sizes. Nutritional information about calories, saturated fat, fiber, and sodium was collected by visual inspection of the products' nutrition facts labels. Unit value per serving was calculated as a proxy for price, by dividing the value of sales by the quantity of servings sold, which was computed as the package size divided by the serving size⁷ and multiplied by the quantity of units sold.

[Figure 1. Allocation of Supermercados Toledo branches in Mar del Plata, Argentina]

Information on the distribution of demographics was obtained by sampling individuals from the *Encuesta Permanente de Hogares* (EPH), which is carried out by the *Instituto Nacional de Estadísticas y Censos* (INDEC) in several cities of the country; in this paper I use the information about households of Mar del Plata. The socioeconomic variables of interest are per capita income and average age of the household members, which is related with both household size and presence of children.

In order to match both data sets it is necessary to define the criterion for aggregating sales data and sampling simulated individuals, i.e. to define a market. Since the EPH does not provide the geographical location of surveyed households, it is not possible to define a market as a combination of a geographical area and a unit of time, as in most previous work, which in our case would be a branch-month combination. Therefore, a market was defined as an income-month combination, and the data were prepared following three steps. First, the per capita average income of each Mar del Plata census tract was calculated using data from a household survey.⁸ Second, the potential customers of each supermarket branch were identified according to the population of the census tract in which the branch is located. Finally, the branches were classified by the income level of their potential buyers (high, upper-middle, middle, lower-middle, and low)⁹, and sales data of branches with the same income level were aggregated by month and product. Thus, the data were structured in 270 markets (5 income levels by 54 months) and 2,145 observations (considering different products sold in each market). The demographic characterization of each market was accomplished by randomly drawing simulated individuals from the corresponding period and quintile of the EPH.¹⁰

Lastly, to calculate the market shares it is necessary to assess the market size, i.e. the total potential demand for FFP of the supermarket chain. This was obtained as the 35%¹¹ of the total potential demand of the city, which in turn was calculated by imputing the FFP consumption frequency of "real consumers"¹² to the entire city population. This was done for each of the branches regarding their potential customers, and then the market size for each income-month combination was calculated. The market share for each product in each market was determined by dividing the quantity of servings sold by the market size.

Table 2 presents the characteristics of the FFP products covered by our scanner database. I assign them an identification number (ID) which I will refer to in the results section. Bastón is the most popular variety followed by noisette, despite its relatively high price. On the other

⁷ According to the Argentine Food Code, the size of a serving of FFP is 85 grams (2.99 oz).

⁸ This data come from a probabilistic 500-household survey about potato consumption conducted in Mar del Plata in June 2009 by the Grupo de Economía Agraria of the Facultad de Ciencias Económicas y Sociales, Universidad Nacional de Mar del Plata, Argentina (Rodríguez et al., 2010).

⁹ These income categories were defined according to the average quintile income of the households surveyed by the EPH in the second quarter of 2009, period in which the potato consumption survey was carried out.

¹⁰ Since the EPH is a quarterly survey, three random samples had to be drawn for each quarter and quintile. The sample size (ns) is of 180 individuals by market.

¹¹ This is the Supermercados Toledo share of total supermarket sales in Mar del Plata, according to the opinion of key actors in the supermarket industry.

¹² This refers to the FFP consumption frequency of those polled in the potato consumption survey who declared they consume FFP.

hand, croquettes and rondelles are the segments with the least market shares. It can be seen that Toledo customers can take advantage of economies of scale in these products, since price per serving decrease as container size increases, at equal value of the other characteristics.

Table 3 reports FFP average prices by segment and income level. For all varieties, prices increase with income; golden longs, rondelles and bastón are the least expensive products in all income levels, and croquettes are the most expensive. The last column shows the percentage difference between average prices in high- and low-income-level markets. Consumers of high income-level face higher prices than consumers of low income-level for any product variety, which suggests the presence of a price discrimination strategy implemented by sellers. Golden longs and smiles are the segments in which the highest surcharges are imposed, while bastón and noisette present the lowest surcharges.

[Table 2. Product characteristics, market shares, and prices]

[Table 3. FFP average prices by segment and income level]

Lastly, Table 4 shows average prices by brand and income level. Such as in the previous table, prices increase with income regardless the brand. Granja del Sol offers the most expensive products on average, while RapiPap FFP are the least expensive options.

[Table 4. FFP average prices by brand and income level]

3.2 Estimation

The key point of the estimation is to exploit a population moment condition that is a product of instrumental variables and a structural error term to form a nonlinear GMM estimator. The main technical difficulties to deal with are related to the computation of the integral in equation (4), and to matching theoretical to observed market shares. Formally, let $Z = [z_1, \dots, z_M]$ be a set of instruments such that $E[Z' \cdot \omega(\theta^*)] = 0$, where ω , a function of the model parameters, is an error term defined below and θ^* denote the true value of this parameters. The GMM estimate is

$$(11) \quad \hat{\theta} = \arg \min_{\theta} \omega(\theta)' Z A^{-1} Z' \omega(\theta)$$

where A is a consistent estimate of $E[Z' \omega \omega' Z]$. Because of the inclusion of product-specific dummy variables as product characteristics (as explained below), the error term is defined as the market specific deviation from the mean valuation of the unobserved product characteristics, $\Delta \xi_{jt}$ ¹³. This error term is computed by solving for the mean utility levels, δ_{jt} , that solve the implicit system of equations

$$(12) \quad s_{jt}(x, p_{jt}, \delta_{jt}; \theta_2) = S_{jt}$$

where $s_{jt}(\cdot)$ is the market share function defined by equation (4) and S_{jt} are the observed market shares. For the Simple Logit Model the solution is equal to $n(S_{jt}) - \ln(S_{0jt})$, while for the full model this inversion is done numerically. Once this inversion has been done, the error term is defined as $\omega_{jt} = \delta_{jt}(x, p_{jt}, S_{jt}; \theta_2) - (x_j \beta - \alpha p_{jt})$. The reason for distinguishing between θ_1 and θ_2 becomes clear now: θ_1 enters this error term, and therefore the objective function, in a linear fashion, while θ_2 enters nonlinearly.

The estimation algorithm implemented to compute the estimates requires the following steps (Nevo, 1998):

¹³ A straightforward approach to the estimation of this model is to define the error term as the difference between the observed and predicted market shares. In this work, I define a structural error term following the estimation method proposed by Berry (1994), which allows one to deal with correlation between the error term and prices. The advantage of working with a structural error is that the link to economic theory is tighter, allowing us to think of economic theories that would justify various instrumental variables (Nevo, 2000b).

- (0) Prepare the data¹⁴. Define a vector of market shares and two matrices of attributes, X_1 and X_2 . X_1 contains the variables that enter the linear part of the estimation, common to all individuals (δ_{jt} in equation (3)). X_2 contains the variables that will have a random coefficient, and therefore will enter the nonlinear part (μ_{ijt} in equation (3)). Draw individuals from the auxiliary database in order to obtain values for the variables in D , and draw values for the random shocks to tastes (v) and to utility (ε).
- (1) For a given value of θ_2 and δ , compute the market shares implied by equation (4). Assuming a Type I extreme-value distribution for ε , market shares are approximated by

$$s_{jt}(p_t, x_t, \delta_t, P_{ns}; \theta_2) = \frac{1}{ns} \sum_{i=1}^{ns} s_{ijt}$$

$$= \frac{1}{ns} \sum_{i=1}^{ns} \frac{\exp(\delta_{jt} + \sum_{k=1}^K x_{jt}^k (\sigma_k v_i^k + \pi_1^k D_{1i} + \dots + \pi_d^k D_{di}))}{1 + \sum_{m=1}^J \exp(\delta_{mt} + x_{mt}^k (\sigma_k v_i^k + \pi_1^k D_{1i} + \dots + \pi_d^k D_{di}))}$$

where s_{ijt} is the probability of individual i purchasing the product j in market t .

- (2) For a given θ_2 , compute the vector δ that equates the market shares computed in step (1) to the observed shares, by solving the system of equations in (12). It can be solved numerically by using a contraction mapping suggested by Berry et al. (1995).
- (3) Determine θ_1 according to the mean valuation computed in step (2), and compute the error term $\omega = \delta - X_1 \theta_1$. Interact ω with the instruments and calculate the value of the objective function $\omega(\theta)' Z A^{-1} Z' \omega(\theta)$.
- (4) Search for the value of θ_2 updating starting values until minimizing the objective function.

3.3 Instruments and product-specific dummy variables

As pointed out, once product dummy variables are included in the regression, the error term is the unobserved (to the researcher) income-month specific deviation from the overall mean valuation of the product. Since I assume that players in the industry observe and account for this deviation (i.e., firms take it into account when setting prices, and it affects consumers' utility and willingness to pay), it will be correlated with prices, and therefore least-squares estimate of price sensitivity, α , will be biased and inconsistent.

Much of the previous work treats this endogeneity problem by using observed characteristics of other products to form instrumental variables (IV's). Characteristics of other products will be correlated with price since the markup of each product will depend on the distance from the nearest neighbor, and if characteristics are assumed exogenous they are valid IV's. However, this is not feasible in this study because there is no variation in each product's characteristics over time and across income levels. Furthermore, this strategy assumes the location of products in the characteristics space is exogenous, which implies treating the characteristics as predetermined, ruling out the possibility of firms to change the product design in response to demand shocks.

Our identifying strategy follows that of Nevo (2001), which in turn use an approach similar to that used by Hausman (1994). Exploiting the panel structure of the data, the identifying assumption is that, controlling for product-specific means and demographics, income-level-specific valuations are independent across income levels (but are allowed to be correlated within an income level). Given this assumption, the prices of the product in other income levels and months (and in other cities) are valid IV's. Since prices are a function of marginal costs, and assuming marginal costs have a common component to all income levels and months, prices of product j in two markets will be correlated (relevance condition). On the other hand, due to the independence assumption they will be uncorrelated with the market-

¹⁴ The actual organization of the data depends on the code used to compute the estimation. I adapted a code developed by Nevo (2000b).

specific valuation of other income levels and months (exclusion condition). According to all this, I use prices in other income levels and months as instruments. Additionally, the data source provides sales data of branches located in other cities (Azul, Balcarce, Miramar, Necochea, Olavarría, and Tandil), so I use the monthly average price of the product in those branches as an IV too.

Regarding the inclusion of product-specific dummy variables as product characteristics, one reason to introduce them is that they improve the fit of the model since I cannot be sure that the observed characteristics capture the entire set of factors that determine utility. But a major motivation is to prevent the mean valuation of the unobserved product characteristics, ξ_j , from being part of the error term. These dummies capture all attributes that do not vary by market, and therefore the correlation between prices and the unobserved quality is fully accounted for and does not require an instrument. Because observable characteristics (except price) do not vary by market either, the taste parameters have to be retrieved by using a minimum distance procedure (as in Chamberlain, 1982). Let d denote the $J \times 1$ vector of product dummy coefficients, X be the $J \times K$ ($K < J$) matrix of product characteristics, and ξ be the $J \times 1$ vector of unobserved product qualities. Then from equation (1)

$$d = X\beta + \xi$$

If we assume that $E(\xi|X) = 0$,¹⁵ the estimates of β and ξ are

$$\hat{\beta} = (X'V_d^{-1}X)^{-1}X'V_d^{-1}\hat{d}, \quad \hat{\xi} = \hat{d} - X\hat{\beta}$$

where \hat{d} is the vector of coefficients estimated from the procedure described in Section 4.2, and V_d is the variance-covariance matrix of these estimates.

Finally, time dummy variables are included in the estimation in order to identify the pure effect of product characteristics on consumer's utility once the time effect is controlled for. This is especially relevant for price parameter estimates because significant inflation rates were verified over the analyzed period.

4. Results

4.1 Demand

This section presents the results¹⁶ from the estimation of the utility parameters and price elasticities. Although this paper focuses on the RCDCM, I also estimate the Simple Logit Model for the sake of comparison and because, due to its computational simplicity, it is a useful tool to examine the importance of the inclusion of product-specific dummy variables, and of instrumenting for price. Table 5 displays the results from three specifications of the Simple Logit Model. In column (i) and (ii) I report ordinary least squares (OLS) regressions. The regression in column (i) includes observed product characteristics, but not product fixed effects, and therefore the error term includes the unobserved product characteristic, ξ_j . Column (ii) incorporates product dummy variables, fully controlling for ξ_j . Finally, column (iii) presents the results from an IV estimation using the instruments mentioned in Section 4.3 and including product fixed effects.

[Table 5. Results from the Simple Logit Model]

The attributes content and calories have statistically significant coefficients in the three specifications. The content coefficient changes sign from positive to negative as the unobserved valuation is accounted for, which gives a more intuitive result since small container sizes are more practical to manipulate and therefore are expected to increase utility. The calories estimates are positive in the three specifications, but their magnitude

¹⁵ This is the assumption required to justify the use of observed characteristics as IV's. Here this assumption is used only to recover the taste parameters and does not impact the estimates of price sensitivity.

¹⁶ The software used to obtain the results in Section 5 are Stata 11.2 and MATLAB 7.0.

decreases as the strategies to solve the endogeneity problem (product fixed effects and instruments) are implemented. They also make the coefficients of McCain, fat, fiber, sodium, bastón, and noisette become significant. On the other hand, smiles variable is always nonsignificant. The estimates of the price coefficients are of the expected sign in the three columns, but the one from the IV regression is higher than the estimated by OLS, as in most previous work. It can be concluded that the effects of including product-specific dummy variables and of using instrumental variables are significant both statistically and economically.

However, as pointed out in Section 3, the Simple Logit Model yield restrictive and unrealistic substitution patterns, and therefore is inadequate for analyzing changes in market structure. To overcome these restrictions, I estimate a RCDCM of demand, whose results are shown in Table 6. The constant term, content, brand, and bastón and noisette segments enter the model linearly; price, nutritional variables, and smiles have random coefficients. While nutritional parameters are assumed to be affected by income, the coefficient of smiles variety is interacted with age. As for price, its coefficient is supposed to depend on both consumer income and age.

The estimates of the mean parameters of the utility function indicate that, on average, consumers' utility increases as the FFP content of fiber and calories increase, and as the content of fat decreases. McCain products were revealed as the least valued FFP. The most popular varieties, bastón and noisette, are valued very differently by the average consumer if compared with the base group (golden longs, rondelles, and croquettes): the valuation of bastón is negative, and the valuation of noisette is positive. The sign of the mean price coefficient is negative as expected, and is higher than those presented in Table 5; this result might be driven by the proper control for demographics and heterogeneity achieved by the full model, which guarantees the validity of the IV's. Finally, content, sodium, and smiles coefficient are statistically insignificant (though of the expected sign). As pointed out in Section 4.3, most of these mean parameters (except the mean price parameter) are estimated by the minimum-distance procedure described above. The ability of the observed characteristics to fit the coefficients of the product dummy variables is measured by using a chi-squared test provided by Chamberlain, which is presented at the bottom of Table 6. This test evaluates a restricted model that sets ξ to zero, and therefore the rejection of this model emphasizes the importance of product fixed effects to control for unobserved characteristics that affect utility.

Estimates of heterogeneity around these means are presented in the next few columns. The results suggest that the marginal valuation of nutritional attributes is accentuated by increasing income; in other words, individuals are more sensitive to the negative effect of fat and sodium as are wealthier consumers, and are also more sensitive to the positive effect of fiber. These results are in line with the literature, according to which high income individuals are more concerned about health and nutrition than low income individuals. Coefficients on the interaction of price with demographics are statistically significant, and indicate that younger and lower-income consumers tend to be more price sensitive. A more elastic demand of younger households might be associated with a low participation of FFP in their diet. Given that household average age decreases with the presence of children, and according to the literature, it could be driven by parents' concerns about their children's health, if FFP are perceived as an unhealthy food. This argument is reinforced by the statistical insignificance of the mean parameter of smiles and its interaction with age, since smiles is a kid-oriented variety.

[Table 6. Results from the full model]

Finally, the effect of random shocks to tastes on price and fat coefficients is nonsignificant, suggesting that the heterogeneity in the coefficients is mostly explained by the included demographics. On the contrary, calories, fiber, sodium, and smiles present statistically significant coefficients, implying that part of the parameter variability (all of it in the cases of calories and smiles) is captured by unobserved individual characteristics. This is especially

interesting for sodium and smiles, since the average effect of these variables on utility is not statistically different from zero, but even so our results indicate there is heterogeneity in preferences for these attributes, driven by unobserved (smiles) or by both observed and unobserved (sodium) demographic characteristics.

Based on the results from the full model, I estimate flexible own- and cross-price elasticity coefficients, which are obtained with the following formulas

$$\eta_{jkt} = \frac{p_{kt}}{s_{jt}} \frac{\partial s_{jt}}{\partial p_{kt}} = \begin{cases} \frac{p_{kt}}{s_{jt}} \int \alpha_{it} s_{ijt} (1 - s_{ijt}) dP_D^*(D) dP_v^*(v), & \text{if } j = k \\ -\frac{p_{kt}}{s_{jt}} \int \alpha_{it} s_{ijt} s_{ikt} dP_D^*(D) dP_v^*(v), & \text{if } j \neq k \end{cases}$$

The estimates are shown in Table 7; each entry (i, j) , where i indexes row and j column, gives the elasticity of product i with respect to a change in the price of j . Since the model does not imply a constant elasticity, this matrix will be different depending on what values of the variables are used to evaluate it; I report the average of each entry over the 270 markets in the sample. All own-price elasticities, shown in the main diagonal, are negative and greater than one in absolute value. Smiles and croquettes, the most specialized products, present the higher coefficients, while the noisette segment has the least elastic demand. As for cross-price elasticities they are all positive, as expected since the products are substitute goods. In general, pairs of products that belong to the same segment show greater coefficients, because they are closer substitutes.

[Table 7. Own- and cross-price elasticities]

Bastón of McCain and FarmFrites have the most elastic demand with respect to changes in the price of other FFP. On the other hand, golden longs and FarmFrites noisette have the least cross-price elasticities. The products whose prices affect other FFP demand the most are bastón of Granja del Sol and McCain; in fact, bastón Granja del Sol prices greatly influence all bastón FFP. On the other hand, the products whose prices are less influential in other FFP purchases are rondelles and FarmFrites noisette. Note that while McCain bastón in small package (ID 1110) is both one of the most influenced and one of the most influential products, FarmFrites noisette in small package (ID 2310) presents the opposite situation, i.e. it has one of the less sensitive demand and its price changes have little effect on other FFP demand. A similar pattern is observed, to a greater or lesser extent, for all the products. Figure 2 shows the relationship between the average of the cross-price elasticities of a product with respect to other FFP prices (sensitivity), and the average of the cross-price elasticities of other FFP with respect to the price of the product (influence).

[Figure 2. Cross-price elasticities: relationship between influence and sensitivity]

Table 8 displays the average of the own-price elasticities by income level. Middle-income households demand for FFP is less elastic than both high- and low-income households demand. This could be related to a higher participation of FFP in middle-income consumers' diet. On the one hand, due to concerns about healthy feeding, high income individuals might discard FFP from their diet. On the other hand, low income consumers could find them very expensive. Correct price discrimination should therefore charge higher prices in branches located in middle-income neighborhoods. This is partially supported by our data since, although in general higher prices are set for higher income neighborhoods, as noted in Section 4.1, FarmFrites and RapiPap FFP are more expensive for lower-middle income consumers, and the most popular segments (bastón and noisette) are as expensive for them as for high income individuals.

[Table 8. Own-price elasticities by income]

4.2 Counterfactual changes in FFP market structure

In this section, I simulate hypothetical changes in the industry structure and evaluate their effect on prices, market shares, and consumer surplus, given the demand parameters estimated in the previous section. I propose two hypothetical scenarios. The first one (Scn 1) is the merger between Alimentos Modernos and Granja del Sol, which is interesting because of McCain strong leadership in the market. On the other hand, considering the high concentration of the market, I propose an industry of single-product firms, i.e. each product is produced by a different firm (Scn 2).

First of all I recover marginal costs per serving using equation (8); then, I configure the ownership matrix that represents the hypothetical market structure, Ω^* , in order to estimate the post-change equilibrium prices and market shares (equation (9)). Both costs and counterfactual equilibrium values are computed for a specific market: high income level in December 2009. Table 9 presents the recovered marginal costs and actual prices, market shares, price-cost margins, and sales in the analyzed market.

[Table 9. Initial equilibrium values in high income – Dec 2009 market]

Croquettes are the FFP with the highest marginal cost among the available products in the market, and the most expensive too, which makes sense since it is the most specialized product. McCain presents higher costs and prices than FarmFrites and RapiPap, but FarmFrites is the firm that charges the highest margins. In spite of being the second most expensive product, McCain noisettes have by far the greatest market share, and therefore McCain is the firm with the highest sales in this market.

In Table 10 I present the counterfactual simulation results on prices, market shares, and sales for the proposed industry structures.

[Table 10. Counterfactual changes in prices, market shares, and sales]

After the merger between the two smaller firms the prices of all products would increase, especially those from the merged companies. The increase of firms' market power leads to higher markups, which explain the higher prices in this scenario. This would cause a drop in the demand (and therefore an increase in the market share of the outside good), which is more pronounced for McCain FFP. Moreover, the sales of all firms would decrease, a result that is consistent with the relatively elastic demand for FFP found in Section 5.1. On the other hand, if the FFP market turned into a single-product firms industry, all prices would decrease. The reduction in prices encourages some consumers who did not buy before to start buying (the market share of the outside good decreases), and hence there would be an increase in the market shares of all products and sales. The lower prices in this scenario have to do with the lack of a portfolio effect: if two products are perceived as imperfect substitutes, a firm producing both would charge a higher price than two separate manufacturers.

To assess how important these changes really are, I evaluate their influence on consumer welfare. Compensating variation, CV_i , was computed for each sampled individual in the analyzed market, as described in Section 3.3. Then I averaged the compensating variation across the sample and multiplied by the number of consumers to get total change in consumer surplus (equation (10)). Total number of consumers was assumed to be 600,000 (the population of Mar del Plata). Table 11 shows the monthly change in consumer welfare implied by each hypothetical scenario; both average individual surplus and welfare change for the entire population of the city are reported. The merger between Alimentos Modernos and Granja del Sol would cause a decrease in the welfare of the consumers of Mar del Plata of \$13,277 a month. If the market turned into a single-product firms industry, the monthly improvement in consumer surplus would rise to \$67,558.

[Table 11. Monthly change in consumer welfare due to hypothetical market structures]

Figure 3 shows the relationship between individual compensating variation and demographic variables. In general, the wealthier and older the individual, the greater the influence of hypothetical changes in market structure on his welfare; the relationship is more evident in the case of the age. These results might be driven by the heterogeneity in price sensitivity. Since younger and lower-income consumers tend to be more price sensitive, they in general stay out of the market by choosing the outside good; therefore it is reasonable to expect that they are less affected by changes in the FFP market structure.

[Figure 3. Welfare change and demographic variables]

4.3 Counterfactual introduction of a new product

In the last decades food safety and food quality concerns have increased worldwide among consumers, which have encouraged the accomplishment of certain quality standards. For example, in the Argentinean processed potato industry some transnational companies have demanded producers to implement Good Agricultural Practices (GAP) protocols. These kind of sustainable practices allow to obtain food products that possess a new attribute, the quality certification, which at present is not identified in their packages, at least when sold in Argentinean domestic markets. However, the potato industry firms could extract more consumer surplus by correctly signaling the GAP attribute through a labeling strategy that makes visible this credence characteristic (Nelson, 1970).

Previous work that analyzes the effect of new goods with a RCDCM defines new products as a different combination of already existing characteristics, that is, those included in the demand estimation. In general, their approach consists of estimating the utility function using data containing sales of the product or attribute of interest, and then evaluating the changes in welfare caused by the withdrawal of the product from the market. Instead, here I analyze the introduction of a product that is new because it possesses an attribute that is not yet available in the market (the GAP label), and therefore its influence on utility cannot be recovered with sales data. However, it is necessary to identify the coefficient of the attribute in the utility function in order to assess changes in consumer welfare, so this coefficient was obtained by performing additional calculations, which are explained in what follows.

The utility function for the hypothetical situation with a new product, $u_i^*(\cdot)$, results from adding a term to the original function which indicates if the product is labeled as produced following GAP protocols:

$$u_{ijt}^* = x_j \beta_i^* - \alpha_i^* p_{jt} + \gamma_i^* GAP_j + \xi_j + \Delta \xi_{jt} + \varepsilon_{ijt}$$

If we knew the stated WTP of consumers for the GAP attribute, we could calculate the GAP coefficient γ_i^* as follows:

$$(11) \quad WTP_i^* = -\frac{\gamma_i^*}{\alpha_i^*} \Rightarrow \gamma_i^* = -\alpha_i^* \times WTP_i^*$$

The first equality in (11) is a well-known result in the literature (Gil *et al.*, 2000; Loureiro & Umberger, 2001).

A measure of the WTP for a GAP-labeled FFP was assessed by employing auxiliary information about consumers' WTP for IPPM potatoes.¹⁷ Since both IPPM and GAP production schemes are closely related, consumers would be willing to pay a very similar amount for both kinds of fresh potatoes. Then, WTP for GAP-labeled FFP is derived from WTP for GAP fresh potatoes in two possible scenarios, each of them postulating different WTP behavior for two consumers' profiles. In the first scenario (Sce1), it is assumed that consumers who purchase FFP were willing to pay for a GAP-labeled FFP the same price premium (in percentage terms) as for GAP fresh potato. On the other hand, the WTP of those who do not purchase FFP would be the half of their WTP for GAP fresh potato. In the second scenario (Sce2), it was assumed that consumers who purchase FFP were willing to

¹⁷ This 500-household survey was conducted in Mar del Plata, June 2009, by the Grupo de Economía Agraria, Facultad de Ciencias Económicas y Sociales, Universidad Nacional de Mar del Plata (Rodríguez *et al.*, 2010).

pay for a GAP-labeled FFP the half of their WTP for GAP fresh potato, while those who do not purchase FFP were not willing to pay an extra price premium for a GAP FFP. Therefore, the first is the more optimistic scenario and the second is the pessimistic one. Once I obtained individual WTP for GAP-labeled FFP in both scenarios, I modeled it as a function of the demographic characteristics of the surveyed consumers

$$(12) \quad WTP_i^* = \overline{WTP} + \phi_1 y + \phi_2 age$$

where \overline{WTP} is the average WTP, and ϕ_1 and ϕ_2 were estimated by performing OLS regression.¹⁸ By replacing (12) in equation (11) the individual GAP coefficient γ_i^* is obtained, so I can now compute the counterfactual introduction of the new product.

I carry out the simulation in the market defined by the income-month combination high income - December 2009. I choose the last month of the sales data for the results to be the most up-to-date as possible, and also because it is close to the date on which the auxiliary survey was held. On the other hand, a high-income market was chosen in order to achieve more sensitive results, since it has been verified that wealthier individuals are more willing to pay for sustainable potatoes (Rodríguez *et al.*, 2010).

In this hypothetical scenario, I postulate that one of the available products now possesses a label identifying it as produced under GAP. I pick bastón of brand FarmFrites sold in packages of 700 gr. (ID 2120), because it is the one with the higher market share in our scanner data, among those offered in the analyzed market.

With the addition of a GAP label, bastón FarmFrites in packages of 700 gr. would improve its market share and sales in both scenarios, although in a lesser extent in the pessimistic one. The market share of the remaining FFP would decrease, even for the other FarmFrites products, and mainly among other bastón FFP. However, the total sales of FarmFrites would rise (Table 12). To evaluate the importance of the introduction of the new product, I computed the compensating variation CV_i . Table 13 shows the monthly change in consumer welfare implied by each hypothetical scenario. In Sce1, the introduction of the GAP-labeled FFP would cause an increase in the welfare of the consumers of Mar del Plata of \$17,810 a month. In Sce2, the monthly improvement in consumer surplus would only rise to \$472.

[Table 12]

[Table 13]

In order to analyze the heterogeneous impact of the counterfactual simulation on consumers' welfare, Figure 4 shows the relationship between the individual compensating variation and demographic characteristics. In general, the older the individual, the greater the individual welfare change due to the hypothetical introduction of the GAP-labeled product. The relationship between CV_i and income seems to be direct too, but is less conclusive.

[Figure 4]

Later, I compute how much the price of the GAP-labeled product could raise maintaining constant the initial level of welfare, assuming other prices constant. In Sce1, the GAP-labeled FFP price would reach a value of \$1.256 per serving, while in Sce2 this maximum price is only \$0.999 per serving. Considering the initial non-label price of \$0.961, these results imply that the highest price increase that could be charged to the labeled product would be \$0.295 for Sce1 and \$0.039 for Sce2, if it is not to reduce initial consumer welfare.

I also calculate the maximum increase in marginal cost that FarmFrites would be able to afford if farmers charge higher prices for fresh potatoes obtained by following GAP protocols. Assuming that the marginal cost of the other products remains constant, the highest affordable marginal cost of the GAP-labeled FFP accounts for \$0.958 and \$0.877 for Sce1

¹⁸ This way of modeling the WTP is reasonable since both income and age are expressed as deviations to the mean, both in the auxiliary dataset from which ϕ_1 and ϕ_2 were estimated, and in the demographic database used to perform the RCDCM estimation and the counterfactual simulation.

and Sce2, respectively. Considering a non-GAP cost of \$0.809, the maximum increase in costs for FarmFrites to make a profitable use of fresh GAP-potatoes would be \$0.151 per serving in Sce1. Analogously, the increase of costs should not exceed \$0.077 per serving in Sce2.

5. Conclusions

This paper makes a contribution to the empirical literature of Random Coefficients Discrete Choice Model of demand, which has been scarcely applied in Argentina, mainly regarding food industries. Besides, the paper contributes to the analysis of a food market which is rapidly growing in developing countries and is starting to play a more relevant role in consumers' diet. The article examines the frozen fried potato (FFP) industry in an important city of Argentina, Mar del Plata. I study the heterogeneity in consumer preferences for FFP attributes, evaluate the effect of changes in market structure on consumer welfare, and develop a new methodology for the evaluation of the introduction of a new product with a new attribute, which combines stated and revealed preferences approaches.

A discrete choice approach is used to analyze the demand for FFP. The results suggest that high income individuals are more concerned about health and nutrition than low income individuals, and that younger and lower-income consumers tend to be more price sensitive. The flexible elasticity coefficients achieved with this method indicate that middle-income households demand for FFP is less elastic than both high- and low-income households demand, which could be related to a higher participation of FFP in middle-income consumers' diet. Then, hypothetical changes in the FFP industry structure are simulated and their effect on prices, market shares, and consumer surplus are evaluated. It also serves to identify the effect of different sources of price-cost margins. On the one hand, a merger between the two smaller firms of the market (Alimentos Modernos and Granja del Sol) would cause an increase in prices and therefore a decrease in consumer welfare. On the other hand, if the market turned into a single-product firms industry, the prices would drop and hence the consumer surplus would increase. Regarding the relationship between individual compensating variation and demographic variables, the influence of the counterfactual changes in market structure would be greater the higher the consumer income and age. Lastly, the proposed methodology for the evaluation of the new good combines the advantages of each preferences approaches: the accuracy of the estimation of the price sensitivity of the revealed preferences approach and the possibility to evaluate unavailable attributes of the revealed preferences approach. Although I found a low impact on welfare due to the still scarce importance of FFP in Argentineans' diet, the results emphasize the importance of both the agronomic issues and consumers' preferences for the success of any strategy that seeks to introduce a credence-attribute product in the food market. The article contributes to the analysis of a market which is rapidly growing in developing countries and, as a consequence, is starting to play a more relevant role in consumers' diet.
